Abstract

The accuracy of Green Function Monte Carlo (GFMC) simulations can be greatly improved by a clever choice of the approximate ground state wave function that controls configuration sampling. This trial wave function typically depends on many free parameters whose fixing is a non trivial task. Here, we discuss a general purpose adaptive algorithm for their non-linear optimization.

As a non trivial application we test the method on the two dimensional Wess-Zumino model, a relativistically invariant supersymmetric field theory with interacting bosonic and fermionic degrees of freedom.

1 Introduction

The traditional algorithms for numerical simulations of Lattice Field Theories are based on the Lagrangian formulation [1] that follows Feynman's idea of representing quantum amplitudes in terms of sums over classical paths. An interesting alternative is the Hamiltonian framework of Kogut-Susskind [2] focusing on the Hamiltonian as the generator of the temporal evolution. To improve numerical efficiency in the evaluation of physical

observables, analytical approximations of the ground state wave function can be successfully exploited. This well known procedure is called Importance Sampling [3] and its key problem is to determine the optimal trial wave function (TWF) within a given class depending parametrically on a set of free parameters.

In this contribution, we review a recently proposed algorithm that solves this problem. It is built upon a standard Green Function Monte Carlo (GFMC) simulation algorithm and is based on a non trivial feedback between Monte Carlo evolution and TWF modifications.

To discuss the method, we present some novel results concerning the calculation of the ground state energy of the supersymmetric $N = 1$ Wess-Zumino model in $1 + 1$ dimensions.

2 Review of Green Function Monte Carlo

GFMC algorithms can be regarded as numerical implementations of the Feynman-Kac formula [4]. In the simple case of Quantum Mechanics, this formula claims that, given the potential $V(q)$ and an initial wave function $\psi_0(q)$, the function

$$\psi(q, t) = E \left(\psi_0(q + W_t) \exp - \int_0^t V(q + W_s) ds \right),$$

(where W_t is the Wiener process) solves the Euclidean Schrödinger equation

$$\partial_t \psi(q, t) = \frac{1}{2} \Delta \psi(q, t) - V(q) \psi(q, t)$$

with initial data $\psi(q, 0) = \psi_0(q)$.

A translation of this formula into a numerical algorithm is straightforward and quantum expectation values over the ground state can be expressed as statistical averages over an ensemble of weighted walkers [5]. As is well known, the weight variance of the ensemble members must be controlled in some way. Here we adopt the Stochastic Reconfiguration algorithm with fixed population size [6]. The finite population size bias as well as walker correlations vanish with increasing number of walkers.

Weight fluctuations are closely related to the noise of measurements and are due to the fact that V is not constant along walker paths. To

significantly improve accuracy one needs to reduce these fluctuations. Importance Sampling is a common strategy to achieve such a noise reduction: the original Hamiltonian $H = \frac{1}{2}p^2 + V(q)$ is transformed into

$$\tilde{H} = e^F H e^{-F} = \frac{1}{2}p^2 + ip \cdot \nabla F + \tilde{V},$$

$$\tilde{V} = V - \frac{1}{2}\Delta F - \frac{1}{2}(\nabla F)^2.$$

$\tilde{H}$ is not canonical, but still allows simulations with minor modifications with respect to the $F \equiv 0$ case [5]. The diffusion of the walkers is driven by a drift term proportional to ∇F while the potential $V(q)$ is replaced by a new potential $\tilde{V}$ that depends on the trial wave function through F . Roughly speaking, a true improvement is reached when $\tilde{V}$ is *more constant* than V along random paths in some way we are going to discuss later on.

3 Adaptive Optimization of the Wave Function

In this Section, we show how the trial wave function F can be optimized dynamically within Monte Carlo evolution. To this aim, we consider a parametric TWF $\exp F(\mathbf{q}, \mathbf{a})$ depending on the state degrees of freedom $\mathbf{q}$ and on a set of free parameters $\mathbf{a}$. After N Monte Carlo steps, a simulation with a population of K walkers furnishes a biased estimator $\hat{E}_0(N, K, \mathbf{a})$ of the ground state energy E_0 that we shall take as a representative observable. $\hat{E}_0$ is thus a random variable such that

$$\langle \hat{E}_0(N, K, \mathbf{a}) \rangle = E_0 + \frac{c_1(\mathbf{a})}{K^\alpha} + o(K^{-\alpha}), \quad \alpha > 0,$$

and

$$\text{Var } \hat{E}_0(N, K, \mathbf{a}) \sim \frac{c_2(K, \mathbf{a})}{\sqrt{N}},$$

where $\langle \cdot \rangle$ is the average with respect to Monte Carlo realizations.

In the $K \rightarrow \infty$ limit, $\langle \hat{E}_0 \rangle$ is therefore exact and independent on $\mathbf{a}$. The constant $c_2(K, \mathbf{a})$ is related to the fluctuations of the effective potential $\tilde{V}$ and is strongly dependent on $\mathbf{a}$. The problem of finding the optimal F can be translated in the minimization of $c_2(K, \mathbf{a})$ with respect to $\mathbf{a}$.

The algorithm we propose [5] performs this task by interlacing a Stochastic Gradient steepest descent with the Monte Carlo evolution of the walkers ensemble. At each Monte Carlo step, we update $\mathbf{a}_n \rightarrow \mathbf{a}_{n+1}$ according to the simple law

$$\mathbf{a}_{n+1} = \mathbf{a}_n - \eta_n \nabla_{\mathbf{a}} \text{Var}_{\mathcal{E}_n} \tilde{V}$$

where $\mathcal{E}_n$ is the ensemble at step n and $\{\eta\}$ is a suitable sequence, asymptotically vanishing.

A non-linear feedback is thus established between the TWF and the evolution of the walkers. The convergence of the method can not be easily investigated by analytical methods and explicit numerical simulations are required to understand the robustness of the algorithm. In reference [5], examples of applications of the method with purely bosonic or fermionic degrees of freedom can be found. In the next Section, we shall address a model with both kinds of fields linked together by an exact lattice supersymmetry.

4 The $N = 1$ Wess-Zumino Model in 1+1 Dimensions and Supersymmetry Breaking

The model we consider is a lattice version of the $N = 1$ Wess-Zumino model previously studied in [7]. On each site of a spatial lattice with L sites, we define a real scalar field $\{\varphi_n\}$ together with its conjugate momentum $\{p_n\}$ such that $[p_n, \varphi_m] = -i\delta_{n,m}$. The associated fermion is a Majorana fermion $\{\psi_{a,n}\}$ with $a = 1, 2$ and $\{\psi_{a,n}, \psi_{b,m}\} = \delta_{a,b}\delta_{n,m}$, $\psi_{a,n}^\dagger = \psi_{a,n}$. The fermionic charge

$$Q = \sum_{n=1}^L \left[p_n \psi_{1,n} - \left(\frac{\varphi_{n+1} - \varphi_{n-1}}{2} + V(\varphi_n) \right) \psi_{2,n} \right],$$

with arbitrary real *prepotential* $V(\varphi)$, can be used to define a semi-positive definite Hamiltonian $H = Q^2$. Its positive eigenstates are automatically paired in doublets connected by Q ; only a Q -symmetric ground state with zero energy can be unpaired. H describes an interacting model, symmetric with respect to Q ; its ground state breaks the symmetry if and only if its energy is positive. We stress that spontaneous supersymmetry breaking can occur even for finite L , because tunneling among degenerate vacua connected by Q is forbidden by fermion number conservation.

We can replace the two Majorana fermion operators with a single Dirac operator satisfying $\{\chi_n, \chi_m\} = 0$, $\{\chi_n, \chi_m^\dagger\} = \delta_{n,m}$ [7]. The Hamiltonian takes then the form

$$\begin{aligned} H &= \sum_n \left\{ \frac{1}{2} p_n^2 + \frac{1}{2} \left(\frac{\varphi_{n+1} - \varphi_{n-1}}{2} + V(\varphi_n) \right)^2 + \right. \\ &\quad \left. - \frac{1}{2} (\chi_n^\dagger \chi_{n+1} + h.c.) + (-1)^n V'(\varphi_n) \left(\chi_n^\dagger \chi_n - \frac{1}{2} \right) \right\} \\ &= H_B(p, \varphi) + H_F(\chi, \chi^\dagger, \varphi) \end{aligned}$$

and describes canonical bosonic and fermionic fields with standard kinetic energies and a Yukawa coupling.

The theoretical problem that we want to address is dynamical breaking of supersymmetry in the above kind of models. At tree level, supersymmetry breaking occurs if and only if $V(\varphi)$ has no zeroes. In $1+1$ dimensions, this picture is known to be unstable with respect to radiative corrections as shown by the analysis of the one-loop effective potential of the scalar field φ . From the non-perturbative point of view, the ground state energy E_0 is the crucial quantity because it vanishes if and only if we are in the symmetric phase. The choice of a Hamiltonian Monte Carlo algorithm is then natural since E_0 is the simplest observable that can be measured with such a technique.

We study two specific examples: the cubic prepotential $V(\varphi) = \varphi^3$, where unbroken supersymmetry is expected, and the family of quadratic prepotentials $V(\varphi) = \lambda_0 + \varphi^2$. In the latter case, at tree level supersymmetry is broken for $\lambda_0 > 0$. Perturbative calculations and previous numerical results [7] suggest that this conclusion does not hold at the quantum level and provide evidence that supersymmetry is broken in the lattice model for λ_0 greater than some negative $\lambda_0^* < 0$ and is recovered for $\lambda_0 \leq \lambda_0^*$. On the other hand, the strong-coupling limit suggests $E_0 > 0$ for all λ_0 , decreasing exponentially for $\lambda_0 \rightarrow -\infty$ [8]; moreover, one can show that, at fixed finite L , E_0 is an analytical function of λ_0 ; this would imply that a symmetric phase is only possible in the $L \rightarrow \infty$ limit.

4.1 Simulation Algorithm: Brief Description

The Monte Carlo evolution in GFMC algorithms approximates the Hamiltonian evolution semigroup $\{e^{-tH}\}_{t \geq 0}$. The bosonic and fermionic degrees

of freedom can be split by writing

$$e^{-\beta H} = e^{-1/2 \beta H_B} e^{-\beta H_F} e^{-1/2 \beta H_B} + \mathcal{O}(\beta^3),$$

and the $\beta \rightarrow 0$ extrapolation is numerically computed at the end. We implement the evolution associated to H_B to second order in β [9] and the evolution associated to H_F exactly [10].

About the choice of the trial wave function, we propose the factorized form

$$|\Psi_0^T\rangle = e^{S_B(\varphi) + S_F(\varphi, \chi, \chi^\dagger)} |\Psi_0\rangle_B \otimes |\Psi_0\rangle_F,$$

where $|\Psi_0\rangle_B \otimes |\Psi_0\rangle_F$ is the ground state for the free model and

$$S_B = \sum_n \sum_{k=1}^{d_B} \alpha_k^B \varphi_n^k, \quad S_F = \sum_n (-1)^n \left(\chi_n^\dagger \chi_n - \frac{1}{2} \right) \sum_{k=1}^{d_F} \alpha_k^F \varphi_n^k.$$

The degrees d_B and d_F must be chosen carefully to achieve convergence of the adaptive determination of $\{\alpha^B, \alpha^F\}$.

In the regime of weak coupling perturbation theory, the choice of periodic boundary conditions does not break supersymmetry when $L \bmod 4 = 0$. Under this condition, there is an even number of fermions, $L/2$, in the ground state. A sign-problem then arises due to boundary crossings since they involve an odd number of fermion exchanges. To avoid such a difficulty, we shall adopt open boundary conditions. With this choice, L needs just to be even to assure a supersymmetric weak coupling ground state. In the following, we shall restrict ourselves to the case $L \bmod 4 = 2$ and to the sector with $L/2$ fermions that contains a non-degenerate ground state, with zero energy at all orders in a weak coupling expansion.

4.2 Numerical Results

We choose $d_B = d_F = 4$; due to the symmetries of the model with quadratic $V(\varphi) = \lambda_0 + \varphi^2$, we impose parity constraints on the trial wave function, setting $\alpha_1^B, \alpha_3^B, \alpha_2^F, \alpha_4^F$ to zero ($\alpha_1^B, \alpha_3^B, \alpha_1^F, \alpha_3^F$ in the cubic case), and determine by the adaptive algorithm the remaining four free parameters. We work on a lattice with 10 spatial sites and vary both K and λ_0 . In principle, we also extrapolate any result to the $\beta \rightarrow 0$ limit. However, the results we present are all obtained with a fixed value $\beta = 0.01$ since we checked that a reduction of this parameter by a factor 2 does not change appreciably the results.

Figure 1: Adaptive Optimization of the four coefficients appearing in the trial wave function for the quadratic model. The constant λ_0 is 0.0 and the ensemble size is $K = 100$.

Beginning with a small ensemble of $K = 100$ walkers, we determine adaptively the four coefficients $\{\alpha_2^B, \alpha_4^B, \alpha_1^F, \alpha_3^F\}$ starting from zero values. A typical run is shown in Fig. (1). For larger K , we start from the values of α obtained in a run at the nearest smaller K . A summary plot of $\{\alpha_2^B, \alpha_4^B, \alpha_1^F, \alpha_3^F\}$ as functions of K and λ_0 is shown in Fig. (2).

With the optimized TWF parameters, we determine the energy contributions coming from the bosonic and fermionic sectors separately. The sum of the two is the total ground state energy E_0 . Apart from the dependence on β , E_0 is a function of three parameters $E_0 = E_0(\lambda_0, L, K)$, where we understand our choice of TWF and also optimization of its free parameters. The dependence on K is totally artificial and we are interested in $E_0(\lambda_0, L, \infty)$. The dependence on L enters the study of the continuum limit of the model. However, here we simply want to test the method and work at fixed $L = 10$.

For the quadratic case, we show in Fig. (3) the behavior of $E_0(\lambda_0, L, K)$ as a function of K at several values of λ_0 . For $\lambda_0 > -0.5$ the K dependence is very mild and one can confirm the claim that a positive $E_0(\lambda_0, L, \infty) >$

Figure 2: Summary plots of the four trial wave function parameters as a function of λ_0 and K .

0 is obtained at $K \rightarrow \infty$. Instead, for $\lambda_0 < -0.5$, there is a certain dependence on K and an extrapolation toward $K \rightarrow \infty$ must be performed to determine the asymptotic limit. Fig. (4) shows the results of such an extrapolation. For $\lambda_0 \geq -1.25$, we can exclude a zero $E_0(\lambda_0, L, \infty)$; for $\lambda_0 \leq -1.5$ our data are compatible with zero.

On the other hand, for the cubic potential the dependence of E_0 on K is relatively mild; in Fig. (5) we show that E_0 is compatible with 0 for $K \geq 500$, in full agreement with the expectation of unbroken supersymmetry. It should be noticed that bosonic and fermionic contributions to E_0 are of the order of 10, and the two are canceling to a precision of 10^{-4} .

The conclusion we can draw from the above numerical data is that the presented algorithm behaves in a completely satisfactory way in the analysis of the $N = 1$ Wess-Zumino model, at least for what concerns the determination of the ground state energy. In the $L = 10$ lattice

 Figure 3: Total energy in log scale as a function of λ_0 and K .

quadratic model supersymmetry is broken with no doubts for values of λ_0 down to about $\lambda_0 \simeq -1.25$. Below this value, E_0 is compatible with zero at the statistical level we work. We remark that around $\lambda_0 \simeq -0.75$ the coefficient α_2^B changes sign, modifying the shape of the TWF and allowing for local minima in its φ -dependent part $S_B(\varphi)$ at non zero fields; we interpret this fact as an interesting signal that some transition is occurring and emphasize the important role that trial wave functions play. On the other hand, for the cubic model the evidence for unbroken supersymmetry is quite convincing.

Unbroken supersymmetry implies a number of non-trivial Ward identities; we monitored several of these, obtaining a pattern of supersymmetry

Figure 4: Extrapolation of the total energy in the $K \rightarrow \infty$ limit. The various curves are drawn for several values of λ_0 . Data points corresponds to $K = 100, 200, 500, 1000, 1700, 3000, 5000$, and 10000 .

breaking perfectly consistent with the one obtained from E_0 , although with lower numerical precision [11].

5 Conclusions

The Hamiltonian approach is a powerful method for Monte Carlo analysis of field models. It is well founded and general purpose, but the control of systematic errors is fundamental. A good trial wave function can improve strongly the quality of numerical results and the convergence rate

Figure 5: For the cubic potential, extrapolation of the total energy in the $K \rightarrow \infty$ limit. Data points corresponds to $K = 100, 200, 500, 1000$, and 2000 .

of simulations. The trial wave function is an approximation to the exact ground state. As such, it contains important physical informations about the model under study. Optimization of (many-parameter) wave functions is thus not only motivated by computational needs only. It affords and checks analytical insights about the actual ground state.

Moreover, as we have shown, for certain models in $1 + 1$ dimensions, the Hamiltonian formalism appears to be the natural framework for lattice fermions. The treatment of bosons and fermions is nicely symmetric and the non-local determinants required in Lagrangian simulations are not required at all. The possibility of preserving exactly a 1-dimensional

supersymmetry algebra is also very appealing.
